Abstract

The ability to generate sufficiently accurate effort estimates can be seen as a key success factor for multi-organizational projects focusing on the development of large and critical software systems. This is caused, for instance, by the need for synchronizing multiple development and verification and validation processes. Paradoxically, effort predictions in the critical software systems domain are still relying on human judgment. This requires much overhead and its reliability depends largely on the expertise and individual preferences of the involved experts. In particular, verification and validation by independent entity (IV\&V) needs an estimation method that supports negotiating and managing IV\&V costs in the context of sparse measurement data and low availability of domain experts. In order to address these problems, in this paper we propose applying a hybrid effort estimation method called CoBRA\textsuperscript{®} for estimating effort for IV\&V of mission-critical software systems. When applied in an industrial context, CoBRA\textsuperscript{®} improved estimation accuracy and precision by about 40\%, on average, compared to experts estimates and OLS regression.

1. Introduction

The average company spends about 4 to 5 percent of its revenue on information technology, with those that are highly IT-dependent - such as financial and telecommunications companies - spending more than 10 percent on it [5]. Now, a great part of those investments is wasted because software organizations are still proposing unrealistic software costs, work within tight schedules, and, in consequence, finish their projects behind schedule and budget (about 50\% of projects), or do not complete them at all (more than 25\% of projects). Moreover, even though projects are completed within a target plan, the functionality and quality of products delivered are usually cut to fit this plan [11]. This indicates that software project planning is a critical success factor of a software project.

Project planning in the safety-critical domain is particularly important and difficult at the same time. Large functional constraint, high quality requirements, and involvement of several independent parties make it much more challenging to plan mission-critical projects than to plan ordinary, non-critical software development projects. In that context, effective synchronizing activities of all involved parties are a key factor for project success. One example activity requiring such synchronization is verification and validation done by an independent organization, or independent verification and validation (IV\&V). A mismatch between the IV\&V plan and the overall project plan may lead to significant delays or (in extreme cases) to the skipping of certain IV\&V activities. In consequence, the whole mission might be exposed to the high risk of a significant loss of money, and, in the worst case, injury or death of people. Yet, comprehensive support for planning and managing IV\&V is missing.

Effort estimation approaches proposed by the research community have traditionally focused on planning and tracking classical, in-house software development. Effort estimation methods that grew upon those objectives focus on providing exact estimates. They do not, however, support an easily understandable, systematic and reliable analysis of the most relevant causal effort dependencies. Even though an accurate prediction is provided, software practitioners have hardly any support to prevent potential project overruns. In the short-term perspective, this would mean a lack of a solid basis for effectively mitigating project risks, and in the long-term perspective, a limited ability to identify process improvement areas and to learn. Moreover, estimation methods promoted by the research community require large data sets, whereas methods commonly employed by industry extensively involve domain experts.

All those aspects significantly reduce the applicability of existing estimation methods in the IV\&V context, where reliable and comprehensive project management has to be provided despite the minimal availability of quantitative data and human expertise.

In this paper, we propose applying the Cost Estimation, Benchmarking, and Risk Analysis method (CoBRA\textsuperscript{®}) [12][17] to estimate the effort of the IV\&V of mission-critical software systems. CoBRA\textsuperscript{®} is a hybrid method that combines analytical and expert-based estimation. It provides a systematic way to transform various sources of organizational knowledge (minimal set of measurement data and expert judgment) into a transparent and reusable effort model that supports achievement of a variety of project management objectives, such as risk management or nego-
tiating of project costs.

The remainder of the paper is organized as follows: Section 2 briefly characterizes the IV&V context. Section 3 gives an overview of existing software effort estimation methods, followed by a more detailed description of the CoBRA® method in Section 4. Section 5 presents the empirical results of an industrial application of CoBRA® for planning the effort of IV&V, followed by lessons learned (Section 6) in the study. The paper ends up with a brief summary and conclusions given in Section 7.

2. Independent Verification and Validation

2.1. Characteristics of IV&V

Independent verification and validation (IV&V) can be defined as a process where software work products generated by a development team are verified and validated by a completely independent organizational entity. Independence is considered here [7] in terms of technical, managerial, and financial independence. IV&V is typically applied in the context of safety- or mission-critical software systems, such as space and nuclear plant systems.

The typical constraint of IV&V, as compared to classical in-house V&V, is limited information on processed artifacts. On the one hand, there is limited knowledge about the software development environment; on the other hand, IV&V has to handle various types of mission-critical systems. This variety does not allow for collecting many historical project data. Moreover, involvement of three sites (customer-, development-, and IV&V-entity) in the software development process contributes to frequent and unpredictable requirements change.

In that context, managing an IV&V project’s resources is critical and difficult at the same time.

2.2. Objectives of Effort Estimation

Besides traditional estimation objectives such as precise planning and tracking software resources, project needs decision-making support. In particular, explicit identification of factors having the greatest impact on IV&V cost and their quantitative impact should be supported. Identification of customer-specific factors (e.g., level of customer support) may be used to justify and negotiate IV&V costs that cannot be influenced by the IV&V supplier. On the other hand, identification of the IV&V supplier’s characteristics (process and human capabilities) that have the greatest impact on increased IV&V costs will allow targeting improvement actions to specific process areas and improving the efficiency of IV&V. In consequence, project risks can be mitigated timely and critical organizational processes can be improved.

2.3. Current Effort Estimation Practices

A survey about current estimation practices at Japan Manned Space Systems Corporation (JAMSS) revealed that measurement data from around 10 already completed projects have been collected within the past 10 years. However, the data suffered from significant incompleteness (around 20% of missing data) and large variability – due to the high uniqueness of the considered projects. Since hardly any data-driven estimation method that would meet the estimation objectives (Section 2.2) can be applied reasonably, estimates are typically based on the judgment of one or more domain experts. Although sparse project data are available, experts based their estimates solely on personal experiences. One of the reasons is that the available simple size measures, such as pages of software requirements document, are believed not to reflect the amount of IV&V effort reliably. Yet, expert-based estimation did not provide satisfactory support for project management. First, the reliability of the estimates depends largely on individual expertise and preferences of involved domain expert. In consequence effort estimates are not accurate and vary widely across projects (see Table 4 and Table 5 in Section 5.5). Moreover, estimation costs much effort each time it is performed, and since it does not provide any explicit effort model, it hardly supports decision making in a project.

3. Related Work

Numerous types of estimation methods have been developed over the last decades. In this section we provide a brief overview of existing estimation methods from the viewpoint of their applicability in the context of IV&V. For a comprehensive review and comparative evaluation of existing methods, please refer to [16].

Existing effort estimation methods differ basically with respect to the type of inputs they require and the form of the estimation model they do provide. With respect to input data, we differentiate between three major groups: data-intensive, expert-based, and hybrid methods (combining available data and expert knowledge in order to come up with estimates). Among the data-intensive methods, some require past project data for building customized models (define-your-own-model approaches), others provide an already defined model, where factors and their relationships are fixed based on a set of multi-organizational project data (fixed-model approaches). The major advantage of fixed-model approaches is that they, theoretically, do not require any historical data to be applied. Those methods might be especially attractive in the IV&V context, where very sparse (if any) data are typically available. Yet, in practice, fixed models, such as COCOMO [2][1], are developed for a specific context (typically different from IV&V) and are, by definition, only suited for estimating the types of projects for which the fixed model was built. The applicability of such models for the IV&V context is, in practice, very limited. In order to improve their performance, a significant amount of organization-specific project data would be required for calibrating the generic model. In that case, the
little usefulness of the fixed-model approaches for IV&V effort estimation would not differ much from the define-
your-own-model approaches, which require a significant
amount of context-specific data to build customized effort
models [15]. Application of the define-your-own-model
methods in the context of IV&V is further limited by the
additional requirements of specific methods. Parametric
approaches, such as regression [14], for instance, make
several assumptions about underlying project data (com-
pleteness, normal distribution, etc.) that are rarely met in
the software domain. Non-parametric methods originating
from the machine learning domain, such as artificial neural
networks (ANN) [3] or Decision Trees/rules [15], make
practically no assumptions about the data but are quite sen-
sitive to their parameter configuration and there is usually
little universal guidance regarding how to set those parame-
ters. Thus, finding appropriate parameter values requires
some preliminary experimentation.

In contrast to data-intensive methods, expert-based es-
timation does not require any project measurement data
because estimates are based on the judgment of one or
more human experts [2]. Expert estimation is, in fact, com-
monly used in the software industry (including IV&V). It
does, however, have several significant limitations. First,
much effort is required each time estimation is performed,
and the reliability of the outputs it provides largely depend
on the expertise and individual preferences of the human
experts involved. Moreover, since the rationale underlying
final estimates is not modeled explicitly, there is hardly any
support for effective decision making in a project (risk
management, process improvement, project scope negotia-
tions, etc.). Recently, a few hybrid methods have been pro-
posed to cope with deficits of data-intensive and expert-
based estimation. They combine a reduced amount of both
measurement data and human expertise to provide more
reliable estimates with limited estimation overhead. Empir-
ical applications [17][10] report on their higher estimation
accuracy and stability when compared to data- or ex-
pert-based methods. Moreover, methods that employ ex-
plicit causal effort modeling (e.g., CoBRA® [17]) have
proven to greatly contribute to the achievement of a variety
of organizational objectives, such as risk management or
process/productivity improvement.

4. The CoBRA® Method

CoBRA® [12][15] is a hybrid method combining data-
and expert-based effort estimation approaches. CoBRA®
the method is based on the idea that project effort consists
of two basic components: nominal project effort and an
effort overhead portion as presented below.

Nominal effort is the effort spent only on developing
a software product of a certain size in the context of a hypo-
thetical “ideal” project that runs under optimal conditions;
i.e., all project characteristics are the best possible ones
(“perfect”) at the start of the project. Effort overhead is the
additional effort spent on overcoming the imperfections of
a real project environment, such as insufficient skills of the
project team. In this case, a certain effort is required to
compensate for such a situation, e.g., team training has to
be conducted. In CoBRA®, effort overhead is modeled by a
causal effort model that consists of factors affecting project
effort within a certain context. The causal model is ob-
tained through expert knowledge acquisition (e.g., involv-
ing experienced project managers).

\[
\text{Effort} = \text{Nominal Productivity} \times \text{Size} + \text{Effort Overhead}
\]

\[
\text{Effort Overhead} = \sum_{i} \text{Multiplier}_{i} \times (\text{Effort Factor}_{i}) + \sum_{j} \text{Multiplier}_{j} \times (\text{Indirect Effort Factor}_{j})
\]

An example is presented in Figure 1. The solid and
dashed arrows indicate direct and indirect relationships,
respectively. For instance, Requirements volatility has a
direct impact on development effort. The strength of this
negative influence on effort may, however, be modified
(compensated) by Disciplined requirement management
(indirect influence). The effort overhead portion resulting
from indirect influences is represented by the second com-
ponent of the sum shown in (2).

![Figure 1: Example of a Causal Effort Model](image)

The influence on effort and between different factors is
quantified for each factor using experts’ evaluation. The
influence is measured by means of effort overhead, i.e., a
relative percentage increase of the effort above the nominal
project. In order to capture the uncertainty of evaluations,
experts are asked to give three values: the maximal, mini-
mal, and most likely cost overhead for each factor (triangu-
lar distribution).

The second component of CoBRA®, the nominal project
effort, is based on data from past projects that are similar
with respect to certain characteristics (e.g., development
type, life cycle type) that are not part of the causal model.
These characteristics define the context of the project. Past
project data is used to determine the relationship between
cost overhead and costs (see equation #1). Since it is a sim-
ple bivariate dependency, it does not require much meas-
urement data. In principle, merely project size and effort
are required, whereby both can be measures using any valid
metric representing project size and effort.
Based on the quantified causal model, past project data, and current project characteristics, an effort overhead model is generated using a simulation algorithm (e.g., Monte Carlo). The probability distribution obtained could be used further to support various project management activities, such as effort estimation, evaluation of effort-related project risks, or benchmarking. More details regarding the CoBRA® method can be found in [12][15].

5. Case Study
5.1. Context of the Study
The study was performed in the context of JAMSS, a company that performs IV&V of space software systems (embedded software domain). JAMSS has been, for instance, supporting IV&V for critical space software systems created by the Japan Aerospace Exploration Agency (JAXA) for more than 10 years.

In this study, we focused on IV&V of the software requirements specification documents using the document review technique. The document review process starts with a risk analysis to identify a software system’s operational risks. Software requirements are then reviewed in more detail based on their operational risks with respect to one or more review objectives. In principle, there were six review objectives [8] (Table 2): (O1) risk analysis, (O2) state transition completeness and consistency, (O3) design completeness for exceptional behavior, (O4) timing correctness and consistency, (O5) interface correctness and consistency, and (O6) traceability.

There were three domain experts involved in the study (Table 1) who provided their knowledge to build the effort overhead model. The main fields of expertise covered by involved experts included: software product quality & safety assurance (SPQSA), software safety reviews (SR), and safety assurance in operation (SAO).

As project measurement data, the number of document pages was selected as the size of a software requirement because even if the complexity of a requirement complexity is related to the effort for reviewing a document, the document itself has to be read by the IV&V team in order to find out what this complexity is.

IV&V effort data from five projects were collected for each project. In practice, because some IV&V objectives were not addressed, effort data were not collected for each IV&V objective except for one project. Therefore, weekly working statuses of IV&V were used to abstract the effort for each IV&V objective. Measurement data available for the estimation included size and effort. Size was measured in pages of software requirements for objectives O1 to O5 and system specification (software and hardware) for objective O6 additionally. The effort was measured in person-days (PD).

5.2. Study Objectives
The objective of the study was to validate accuracy and precision of CoBRA® in the context of JAMSS IV&V (compared to expert judgment and Ordinary Least Squares method) and its contribution to the achievement of defined organizational objectives (Section 2.2).

5.3. Study Design
5.3.1. Effort Estimation Procedure
Motivated by its numerous benefits, the CoBRA® Method was proposed as best fitting the effort estimation capabilities and objectives of JAMSS. First of all, CoBRA® proposes a systematic way to build an explicit and reusable effort model based on both implicit knowledge of domain experts and sparse measurement data. Moreover, it provides on the output a transparent and intuitive model of causal effort dependencies specific for the context where it was applied. The first step of the effort estimation procedure included development of the CoBRA® model using the knowledge of the involved domain experts and measurement data (size and effort) from already completed (historical) projects. For each of the six IV&V objectives specified in the study (Table 2), a separate CoBRA® model was developed. After the CoBRA® models had been created, each was validated on the historical data in a leave-one-out cross-validation experiment.

5.3.2. Study Hypotheses
In order to effectively support achievement of the estimation objectives, the outputs of CoBRA® need to be reliable. In our study, we evaluate reliability by validating the predictive performance of the estimation outputs, measured in terms of predictive accuracy and precision. We expect that CoBRA® will outperform the currently employed expert-based estimation as well as the Ordinary Least Squares method (OLS), one of a few data-driven methods that are applicable in the study context (due to very sparse measurement data). This leads us to two study hypotheses:

**H1.** CoBRA® provides more accurate and more precise estimates than estimation based on expert judgment.

**H2.** CoBRA® provides more accurate and more precise estimates than estimation based on OLS.
5.3.3. Evaluation of Estimation Performance

The effort models created in the study effort models were evaluated with respect to their predictive performance. We define predictive performance as the ability of the effort model to provide accurate and precise estimates. Estimation accuracy refers to the nearness of an estimate ($\hat{E}$) to the true value ($E$). In order to remain comparable to other estimation studies, we use common estimation error measures and accuracy measures [4], such as relative error ($RE$ in equation #3) and mean magnitude of relative error (MMRE).

$$RE_i = (\hat{E}_i - E_i) / E_i$$  \hspace{1cm} (3)

The Conte’s RE and MRE measures are the subject of common criticism in the software research community [6]. One of the alternative measures of estimation error proposed is the so-called $z$ measure (equation #4) [6]. It quantifies the ratio of the estimate to the actual value

$$z_i = E_i / \hat{E}_i$$  \hspace{1cm} (4)

Estimation precision refers to the degree to which several estimates are very close to each other (i.e., the scatter in the data). For the purpose of comparability to other studies, we adopt the $Pred.m$ measure. The $Pred.m$ measures the percentage of estimates that are within $m\%$ of MRE [4]. In our study, we use $m = 25\%$ as typically employed in software estimation studies. Moreover, we adopt relative standard deviation (RSD) (5) proposed by [6] for software effort estimation as uncorrelated with size ($S_i$) (which is a weakness of classical standard deviation measures).

$$RSD = \sqrt{\frac{\sum_i (E_i - \hat{E}_i)^2 / S_i^2}{n - 1}}$$  \hspace{1cm} (5)

5.4. Study Execution

During the study execution, six CoBRA® models were created for each of the IV&V objectives. For each model, domain experts identified several factors (Table 3) that are responsible for the variance of IV&V efficiency for a certain objective (Figure 2).

5.5. Results and Interpretation

This section presents the results of the empirical study. Table 4 and Table 5 present the aggregated measures of the predictive performance. In order to test the significance of the observed effects, appropriate statistical test were performed [13] (at $\alpha = 0.05$). The results of a Shapiro-Wilk W test indicated that the MRE and $z$ results come from normal population; in that case, a parametric Paired T-test for homogeneity of means was used. Since the RSD data violated the normality assumption, a non-parametric Wilcoxon Matched-Pairs Signed Rank test was used. Note that expert estimates were available for a subset of the past projects considered (indicated as $n$ in Table 4 and Table 5). Finally, as we were afraid that for such a small data sample, statistical tests would not have enough power ($\beta - 1 \geq 80\%$), we performed a power analysis.

5.5.1. Hypothesis $H1$

The results of the empirical investigation (Table 4) suggest that, in principle, CoBRA® provides noticeably more accurate estimates than either expert judgment or OLS for all considered IV&V review objectives (a few exceptions are marked in gray). For example, it improves MMRE by 70% and 40%, on average, compared to OLS and domain experts, respectively. Only few of the obtained results are statistically significant at the chosen $\alpha$ level (marked in bold). As expected, in most of the cases, statistical significance testing did not provide meaningful results ($\beta - 1 << 80\%$). The only powerful results are marked in italics. Summarizing, we conclude that hypothesis $H1$ is valid.

5.5.2. Hypothesis $H2$

The analysis of estimation precision (Table 5) suggests that, in principal, CoBRA® noticeably outperforms both expert judgment and OLS for all considered IV&V review objectives (a few exceptions are marked in gray). For example, it reduces RSD by 54% and 40%, on average compared to OLS and domain experts, respectively. Similar to accuracy, in most of the cases, statistical significance test-
ing did not provide meaningful results ($\beta_1 << 80\%$). Summarizing, we conclude that hypothesis H2 is valid.

5.6. Threats to Validity

Several threats to the validity of the presented case study were identified. First, the very sparse project measurement data available prevented us from achieving sufficient power of performed statistical tests. Moreover, expert estimates used to compare CoBRA®’s performance were available only for some of the past projects considered in the study. Finally, the conclusions drawn in the study are limited to the specific context of IV&V reviews at JAMSS. Generalization of the study findings requires further replications.

6. Lessons Learned

The following practical lessons were learned while applying the CoBRA® method for estimation effort of IV&V:

(L.L1) Effort estimation scope: Since IV&V activities differ depending on the objective of IV&V, the scope of effort estimation (the context for which an effort model is built) should be limited to a single IV&V objective. Total effort is the sum of effort over all objectives.

(L.L2) Size and complexity of review: The complexity of a document under review should be considered as an effort driver beyond simple size measures, such as number of document pages.

(L.L3) Effort drivers: Considering effort drivers other than size is a very important aspect of effort modeling. We experienced that a single factor may multiply effort by as much as 10 times (e.g., a complete lack of risk assessment already done by a software supplier may increase the effort of independent risk analysis by up to 20 times). Such an effect is impossible to investigate based only on historical size and effort data.

7. Summary

In this paper, we proposed adapting the CoBRA® software estimation method to predict the effort of independent verification and validation (IV&V). The method provides a potential solution to estimation problems in the context of IV&V. By integrating data- and expert-based estimation, CoBRA® requires minimal amounts of project measurement data and reduces the involvement of domain experts. As a result, it provides a reusable model that supports strategic project/process objectives, such as risk management for effort overrun for each IV&V objectives. At the same time, as reported by several empirical studies, it provides accurate and precise estimates.

When applied in the context of an example IV&V organization, CoBRA® proved to provide more reliable estimates than both the expert-based estimation currently applied and ordinary regression (OLS) - one of few data-intensive methods applicable in the IV&V context. It improved the accuracy and precision of estimates by 40%, on average. At the same time the method provided a transparent, context-specific effort model that supported IV&V practitioners in achieving project and process management objectives (e.g., negotiating project scope or improving the effectiveness of IV&V activities).
